A 61-year-old male, ECOG-PS scale 2, smoker, who was homeless and had no medical history, presented to the emergency department with breathlessness at rest, yellow sputum and hoarseness. Thoracic computed tomography revealed centrilobular emphysema and a right hilar mass (79 × 39 mm) invading the mediastinum, associated with irregularity in the calibre of the right main bronchus (RMB). Flexible bronchoscopy showed an infiltrative lesion at the entrance of the RMB extending into the main carina and upper third of the left main bronchus (LMB). Also, a wide fistula at the RMB with approximately 2 cm in diameter was noted (Fig. 1), providing visualization of the ipsilateral lung parenchyma. Bronchial biopsies of the infiltrative lesions at the main carina and LMB evidenced squamous cell lung carcinoma, PD-L1 50–60%. TNM staging was T4N2M1a (pleural invasion). Considering patient's general status and clinical condition, he was started on palliative treatment with pembrolizumab. The patient died one month after starting immunotherapy due to post-obstructive pneumonia with associated septic shock.

This is a case of main bronchus fistula in the context of mediastinal invasion by a large cavitated squamous cell carcinoma. A main bronchus fistula with endobronchial visualisation of the lung parenchyma and its bronchi is a rare condition in the absence of prior surgery and dehiscence.¹ Additional concern should be addressed to potential problems associated with these fistulas, namely

the risk of bacterial colonisation/infection, pulmonary flooding and pneumothorax.^{2,3}

Oncological treatment of lung cancer may play an important role in preventing bronchial fistula enlargement. However, bronchial fistulas may worsen following specific oncological treatments. In addition to clinical conditions as chronic obstructive pulmonary disease, diabetes mellitus, hypoalbuminemia or liver cirrhosis, radiotherapy stands out as the oncological treatment with the greatest potential to promote the occurrence or enlargement of bronchial fistulas. This risk seems dose-dependent and greater for doses higher than 5.000Gy.³ Neoadjuvant treatment with chemotherapy and/or immunotherapy is also an established risk factor for post-operative bronchial fistula.⁴⁻⁶ Although uncommon, pembrolizumab monotherapy also has the potential to cause or worsen bronchial fistulas, which occurred in 1 of 300 patients assessed in an analysis of real-world data.⁷ It is therefore imperative to provide close clinical and imaging follow-up of these patients and, whenever indicated, to consider interventional bronchology or referral to a specialised thoracic surgery team.

Ethical considerations

Written informed consent was obtained from this patient.
