Social profile of the highest tuberculosis incidence areas in Portugal

Dear Editor,

With a tuberculosis (TB) prevalence of over 20 cases per 100 000 individuals, Portugal is one of the countries with the highest TB burden in the European Union.^{1–3} From 1999 to 2011, TB incidence in Portugal showed a consistent decrease of 4.3% per year, leading to a total decline of 52.1%² and to the disappearance of high incidence regions (≥ 50 cases/100 000 inhabitants).⁴ Despite this progressive decline, the country's heterogeneity is remarkable and the districts of Oporto, Lisbon and Setubal still have an intermediate incidence of Tuberculosis (>20 cases/100 000 and <50 cases/100 000 population). Couceiro et al.³ showed that high risk of TB in some areas of Portugal was related to the high prevalence of HIV/AIDS, incarceration, nonstandard and/or crowded accommodation, unemployment and immigrant populations from countries with high TB incidence. A concentration of young adults might also contribute to the increase of the number of TB cases since the incidence is highest in individuals aged 25–44 years.^{3–5}

Realizing the importance of the social determinants in the control of TB, the authors wanted to characterize the profile of the Portuguese regions with higher incidence rates. The analyzed demographic and socio-economic factors included the population density, proportion of people at working age (15–64 years old), proportion of immigrants and unemployment rate and the TB incidence between 2002 and 2012 in Greater Oporto, Greater Lisbon and Setúbal Peninsula.

The territorial unit used was NUTS 3 (Nomenclatura das Unidades Territoriais para Fins Estatísticos). New TB cases were identified from the tuberculosis national surveillance system; unemployment rate values were obtained from the Employment and Vocational Training Institute reports and the remaining data were collected from National Statistics Institute database. The number of immigrants was only available from 2008 to 2012.

Greater Oporto presented the highest incidence of TB, followed by Greater Lisbon and Setúbal Peninsula. Until 2008, the decline of the incidence rate was

higher in Oporto (81.16–37.69/100 000) than in Lisbon (63.82–35.10/100 000) and Setúbal (55.62–27.73/100 000). From that time onwards, the incidence curves became less pronounced and the three regions assumed closer values (34.39/100 000 in Setubal, 39.52/100 000 in Lisbon and 43.68/100 000 in Oporto) (Fig. 1). Also, from 2008 onwards, the decline of people of working age started to accelerate and the unemployment rate, which had been decreasing since 2002, showed a trend variation and started to increase.

Regarding Oporto area, we can see that during the period studied the population density remained stable (1513.8–1522.5 population/km²), and the proportion of people of working age (69.9–68.1%) and the proportion of immigrants (1.8–1.6%) decreased while the unemployment rate (7.0–13.4% of the labor force) increased. The Lisbon area presented the highest population density (1568.1–1625.4 population/km²) with a definite increase over the years and the highest proportion of immigrants (8.8–8.4%). The proportion of people of working age (68.3–64.5%) and unemployment rate (5.5–8.8%) showed the lowest values for the three regions studied. The Setúbal area, although presenting the lowest population density (422.1–452.6 population/km²), exhibited social and demographic characteristics very similar to those of Lisbon – the proportion of people of working age (69.3–65.4%) was quite close to that in Lisbon and the proportion of immigrants (6.0–5.2%) although not as high as in Lisbon was much higher than in Oporto. The unemployment rate (6.4–9.6%) however was higher than the one observed in Lisbon.

It is well known that the TB burden is strongly linked to socio-economic factors. From 2008 to 2012 there has been a slowing down in the decrease in the Portuguese TB incidence rate, in which the European and the national economic crisis have had an important role. In order to reach long-term TB control targets, efforts to address TB risk factors and social determinants are needed.^{6,7} When looking at the three areas with the highest incidence in Portugal – all urban centers – we can see that they have different social profiles. Despite being the second largest urban center of the country, Oporto presents a lower number of individuals from qualified socio-economic groups with higher education⁸ and a higher unemployment rate than Lisbon. The latter is the main entry point for immigrants, many of them

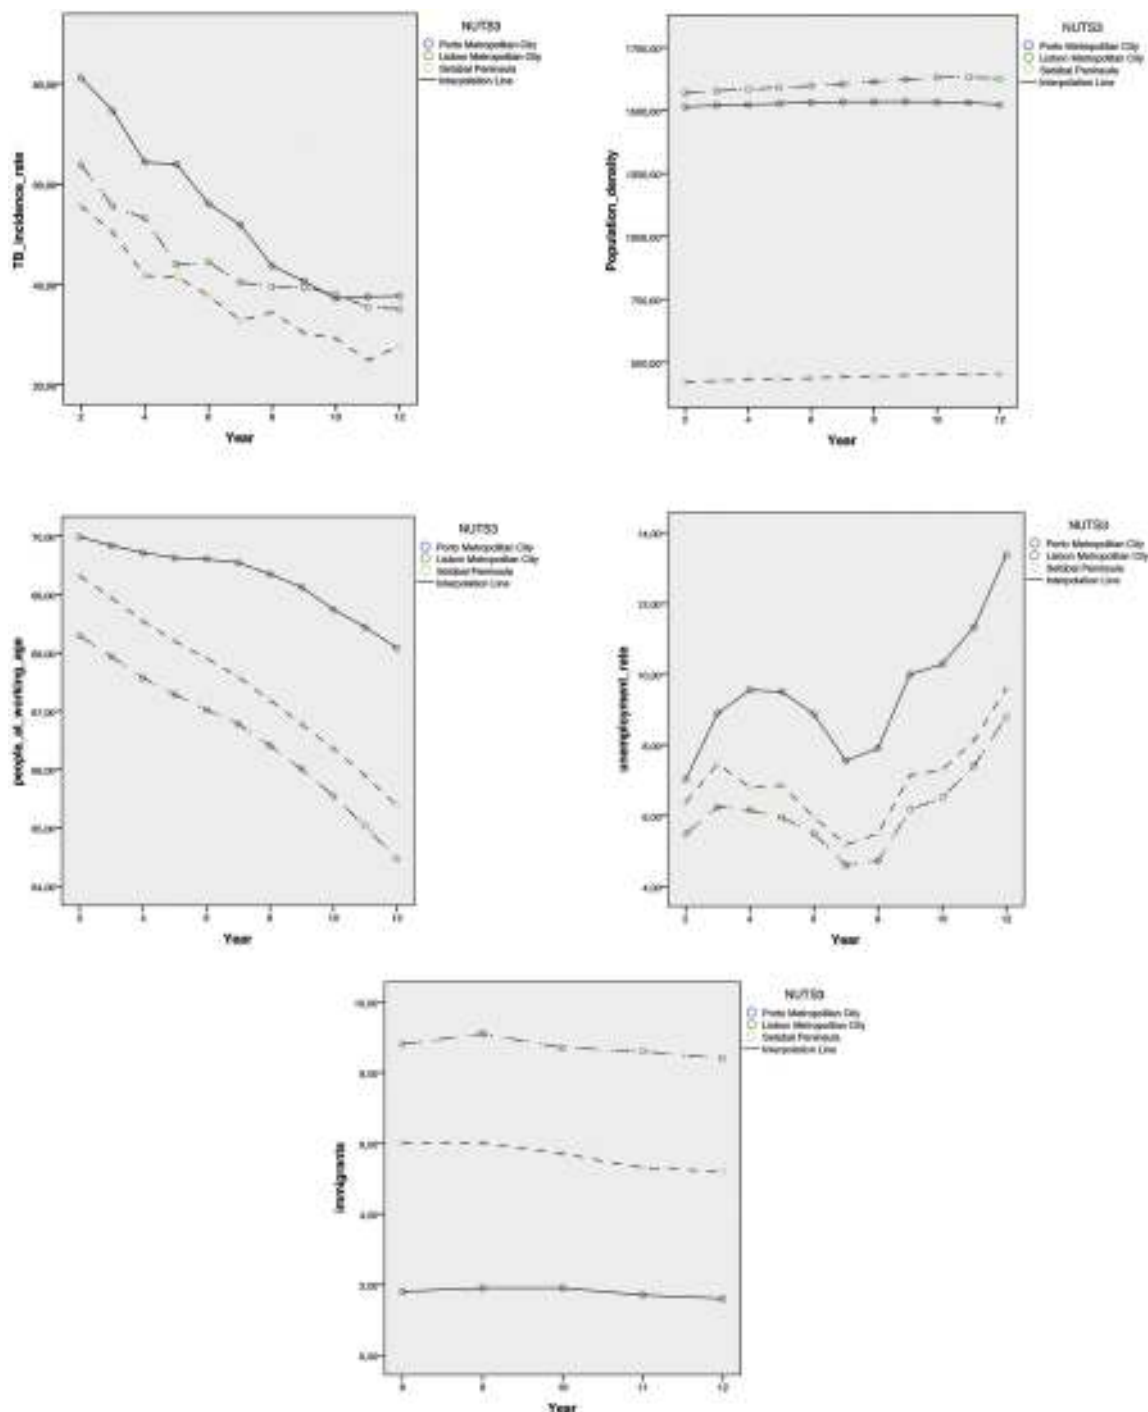

Figure 1 Variation of tuberculosis incidence rate, population density, proportion of people at working age and unemployment rate between 2002 and 2012, and proportion of immigrants between 2008 and 2012, in Greater Oporto, Greater Lisbon and Setúbal Peninsula.

from sub-Saharan African countries with high TB incidence. Although less populated, Setúbal presents a considerable proportion of immigrants and a high unemployment rate due to its proximity to Lisbon. In these settings, TB control requires social, economic and environmental interventions that should be tailored according to each region profile: in Oporto the unemployed population must be addressed

whereas in Lisbon and Setúbal the immigrant population is more relevant.

Conflicts of interest

The authors have no conflicts of interest to declare.

Preoperative pulmonary function and respiratory muscle strength in Portuguese adolescents with idiopathic scoliosis

Dear Editor,

Idiopathic scoliosis is a 3-dimensional deformity of the spine, with direct effects on the thoracic cage, characterized by the lateral displacement (greater than 10°) and rotation of vertebral bodies during periods of rapid somatic growth.¹ Adolescent idiopathic scoliosis (AIS) is found between the age of 10 and skeletal maturity² and its prevalence is estimated at 2–4% in children between 10 and 16 years of age.^{2,3} This condition encompasses several complications including back pain, poor body image, and impaired pulmonary function.³ In fact, previous studies have shown a decreased pulmonary function in adolescents with idiopathic scoliosis,⁴ and an inverse correlation between scoliosis Cobb angles and pulmonary function.⁴ Adolescents with severe scoliosis, with Cobb angles above 45–50°, are routinely managed with spinal fusion surgery.³ In addition to the mechanical restriction to ventilation, changes in spine and thoracic cage position may alter the length of respiratory muscles influencing the ability to generate tension. Therefore, the aim of this study was to evaluate pulmonary function and respiratory muscle strength in subjects with AIS.

From November 2012 to May 2013, 12 females with AIS (15.1 ± 1.6 years of age) and 12 age-matched controls (15.2 ± 1.4 years of age) were enrolled in this study. The AIS group was recruited in the Paediatrics Department of Centro Hospitalar Porto-Hospital Santo António, Portugal, whereas

the control group was recruited in the Porto metropolitan area. Eligible participants were those idiopathic scoliosis preoperative patients aged 10 or over, with thoracic Cobb angles of ≥40°. Exclusion criteria for this study included bronchial asthma and other pulmonary, cardiovascular or skeletal muscle problems, and previous spinal surgery. The study procedures were in accordance with the ethical standards on human experimentation. Written informed consent was obtained from parents/guardians. The Ethics Committee of the Centro Hospitalar Porto-Hospital Santo António approved the study. Lung function and respiratory muscle strength were measured before surgery. Forced expiratory volume in one second (FEV₁), forced vital capacity (FVC), peak expiratory flow (PEF) and the fraction of FVC expired in one second (FEV₁, FVC%) were assessed using a computerized spirometer (Spirolab III, MIR Medical International Research, Roma, Italy), according to standard methods.⁵ Maximal inspiratory pressure (MIP) and maximal expiratory pressure (MEP) muscle strength was measured with a digital mouth pressure meter (Micro Respiratory Muscle Analyze, CareFusion, Basingstoke, UK).⁶ Data were analyzed using SPSS 17.0. The normality of data distribution was tested with the Shapiro–Wilk test; the data were not normally distributed. Groups were compared by Mann–Whitney *U* tests. Associations between pulmonary function and respiratory muscle strength were tested with Spearman’s rho test. The level of significance was set as $P \leq 0.05$.

In terms of the results, the Cobb angle ranged from 42° to 62°. The AIS group presented significantly lower FEV₁, FVC and PEF than the age-matched control group (Table 1). With respect to the respiratory muscle strength, both MIP and MEP were significantly higher in the control group; indeed, the median values of MIP and MEP in the control group were two times higher than those in the control group (Table 1).
